COSE212: Programming Languages

Lecture 7 — Design and Implementation of PLs (3) Lexical Scoping of Variables

Hakjoo Oh 2023 Fall

Goal

Understand lexical scoping in a more systematic way.

- Variable declaration and use
- Scoping rule
- Lexical address
- Nameless representation

References and Declarations

In programming languages, variables appear in two different ways:

- A variable *reference* is a use of the variable.
- A variable *declaration* introduces the variable as a name for some value.
- Examples:

(f x y) proc (x) (x + 3) let x = y + 7 in x + 3

• We say a variable reference is *bound by* the declaration with which it is associated, and that the variable is *bound to* its value.

Scoping Rules

- Every programming language has some rules to determine the corresponding declaration of a variable reference. Called *scoping rules*.
- Most programming languages use *lexical scoping* rules, where the declaration of a reference is found by searching outward from the reference until we find a declaration of the variable:

• We can determine the declaration of each variable reference without executing the program.

Static vs. Dynamic Properties of Programs

- Properties of programs are classified into static and dynamic properties.
- Properties that can be computed without executing the program are called *static properties*.
 - ex) declaration, scope, etc
- Properties that cannot be computed without executing the program are called *dynamic properties*. Dynamic properties are only determined at run-time.
 - ex) values, types, the absence of bugs, etc.

Example: Lexical Scopes of Variables

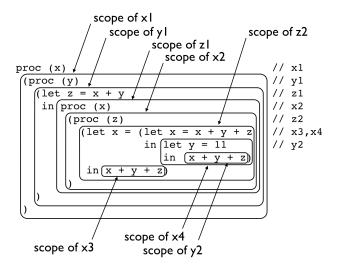

Declarations have limited *scopes*, each of which lies entirely within another:

```
proc (x)
                                          // x1
                                          // y1
 (proc (y)
   (let z = x + y)
                                          // z1
                                          // x2
    in proc (x)
                                         // z2
        (proc (z)
          (let x = (let x = x + y + z / / x3, x4)
                    in let y = 11 // y2
                        in x + y + z)
           in x + y + z)
        )
   )
 )
```

6/16

Example: Lexical Scopes of Variables

Declarations have limited *scopes*, each of which lies entirely within another:

Lexical Address

- Execution of the scoping algorithm can be viewed as a search outward from a variable reference.
- The number of declarations crossed to find the associated declaration is called the *lexical depth* of a variable reference.

```
let x = 1
in let y = 2
in x + y
```

- The lexical depth of a variable reference uniquely identifes the declaration to which it refers.
- Therefore, variable names are entirely removed from the program, and variable references are replaced by their *lexical address*:

```
"Nameless" or "De Bruijn" representation.
```

Examples: Nameless Representation

```
• (let a = 5 in proc (x) (x-a)) 7
• (let x = 37
    in proc (y)
        let z = (y - x)
        in (x - y)) 10
```

Lexical Address

• The lexical address of a variable indicates the position of the variable in the environment.

Nameless Proc

Syntax

$$\begin{array}{rcrcrc} P & \rightarrow & E \\ E & \rightarrow & n \\ & \mid & \#n \\ & \mid & E+E \\ & \mid & E-E \\ & \mid & \text{iszero } E \\ & \mid & \text{if } E \text{ then } E \text{ else } E \\ & \mid & \text{let } E \text{ in } E \\ & \mid & \text{proc } E \\ & \mid & E E \end{array}$$

Nameless Proc

Semantics

$$\begin{array}{rcl} Val &=& \mathbb{Z} + Bool + Procedure\\ Procedure &=& E \times Env\\ Env &=& Val^* \end{array}$$

$$\begin{array}{rcl} \hline \rho \vdash n \Rightarrow n & \hline \rho \vdash \#n \Rightarrow \rho_n & \hline \rho \vdash E_1 \Rightarrow n_1 & \rho \vdash E_2 \Rightarrow n_2 \\ \hline \rho \vdash n \Rightarrow n & \hline \rho \vdash \#n \Rightarrow \rho_n & \hline \rho \vdash E_1 \Rightarrow n_1 & \rho \vdash E_2 \Rightarrow n_2 \\ \hline \rho \vdash E \Rightarrow 0 & \hline \rho \vdash E_1 \Rightarrow n_1 & p \vdash E_2 \Rightarrow n_1 + n_2 \end{array}$$

$$\begin{array}{rcl} \hline \rho \vdash E \Rightarrow 0 & \hline \rho \vdash E \Rightarrow n \\ \hline \rho \vdash \text{iszero } E \Rightarrow true & \hline \rho \vdash E \Rightarrow n \\ \hline \rho \vdash \text{iszero } E \Rightarrow true & \rho \vdash E_2 \Rightarrow v \\ \hline \rho \vdash \text{if } E_1 \text{ then } E_2 \text{ else } E_3 \Rightarrow v & \hline \rho \vdash \text{if } E_1 \text{ then } E_2 \text{ else } E_3 \Rightarrow v \\ \hline \rho \vdash \text{let } E_1 \text{ in } E_2 \Rightarrow v & \hline \rho \vdash \text{let } E_1 \text{ in } E_2 \Rightarrow v \\ \hline \hline \rho \vdash \text{proc } E \Rightarrow (E, \rho) & \hline \rho \vdash E_1 \Rightarrow (E, \rho') & \rho \vdash E_2 \Rightarrow v \\ \hline \rho \vdash E_1 E_2 \Rightarrow v' & \hline \rho \vdash E_2 \Rightarrow v' \end{array}$$

Example

[] ⊢ (let 37 in proc (let (#0 -#1) in (#2 - #1))) $10 \Rightarrow 27$

Translation

The nameless version of a program P is defined to be trans(E)([]):

$$\begin{array}{rcl} \operatorname{trans}(n)(\rho) &=& n\\ \operatorname{trans}(x)(\rho) &=& \#n\\ \operatorname{trans}(E_1+E_2)(\rho) &=& \operatorname{trans}(I\\ \operatorname{trans}(\operatorname{iszero} E)(\rho) &=& \operatorname{iszero}\\ \operatorname{trans}(\operatorname{if} E_1 \operatorname{then} E_2 \operatorname{else} E_3)(\rho) &=& \operatorname{if} \operatorname{tran}\\ \operatorname{trans}(\operatorname{let} x = E_1 \operatorname{in} E_2)(\rho) &=& \operatorname{let} \operatorname{trans}\\ \operatorname{trans}(\operatorname{proc}(x) E)(\rho) &=& \operatorname{proc} \operatorname{trans}(r\end{array}$$

$$\operatorname{trans}(E_1 \ E_2)(\rho) = \operatorname{tr}$$

trans
$$(E_1)(
ho)$$
 trans $(E_2)(
ho)$

Example

trans
$$\begin{pmatrix} (\text{let } x = 37 \\ \text{in proc } (y) \\ \text{let } z = (y - x) \\ \text{in } (x - y)) 10 \end{pmatrix}$$
 ([]) =

Summary

- In lexical scoping, scoping rules are static properties: nameless representation with lexical addresses.
- Lexical address predicts the place of the variable in the environment.
- Compilers routinely use the nameless representation: Given an input program \boldsymbol{P} ,
 - 1 translate it to trans(P)([]),
 - execute the nameless program.
